

DESCRIPTIONPROCESS FOR REDUCING THE PARTICLE SIZE OF POROUS ORGANIC
POLYMERS AND PRODUCTS PRODUCED THEREFROMRelated Applications

This application is a division of application Serial Number 09/167,320, filed October 6, 1998. The earlier filed application is incorporated in its entirety herein by
5 reference.

Background of The Invention

The present invention relates to a process for reducing the mean particle size of resilient porous organic polymer particles having open cell pores, which resist particle size
5 reduction due to the compressibility and resiliency of the organic polymer. Further, the present invention relates to novel products produced by the process for reducing the mean particle size and to particles of reduced mean particle size which have one or more functional agents contained in the
10 pores thereof.

Resilient porous organic polymers resist permanent deformation and have been found to be difficult to process, if at all, for size reduction in conventional grinding
15 processes. Conventional grinding processes are typically used to grind and produce particle size reduction for solid type particles which have little or no compressibility and which can vary in particle hardness. Typical grinding processes such as universal mills, slurry mills, and fluid
20 energy mills, cone mills and hammer mills are generally effective for such solid type particles, particularly brittle type particles. One of the problems with the use of conventional grinding mills for size reduction of resilient porous organic polymers is that the particles compress under the applied forces, i.e., the particles are compressible and

004234 4632260

regain substantially the same geometry when the force is removed. Unlike solid particles, particularly brittle particles, the conventional grinding mill approaches used for dry solid particles produces substantially less or even no size reduction of resilient porous polymers in the dry powder form. Further, attrition type grinding mills have had little overall effectiveness when the organic porous polymers were incorporated into a liquid slurry.

In many applications that use porous organic polymers as additives such as the use of additives in lead acid batteries, it is preferred to have a non-spherical geometry such as an elongated geometry and/or a geometry that has a length to diameter which is greater than one, in order to provide improved overall performance of the additive. It is therefore desirable to produce porous organic particles of reduced size by processes which produce a non-spherical geometry and a higher surface area.

Thus, for the many applications in which porous organic polymers are used, particularly their use as additives, wherein a reduced particle size and/or particle size distribution offers performance advantages, there is a need for a process which is effective for reducing the particle size of resilient porous organic particles at reasonable process conditions and processing times, particularly processing conditions at atmospheric pressure and ambient temperatures at preferably commercial scale processing times.

Brief Summary of the Invention

A new process for reducing the mean particle size of resilient porous organic polymer particles having open cell pores has been discovered. In brief, the process includes the steps of forming an aqueous particle slurry comprising a major amount of water, both internal and external to the particles and a minor amount of particles to form a slurry

and subjecting the aqueous slurry to a cutting action by contact with a plurality of cutting surfaces to reduce the average particle size of the particles and recovering particles of reduced mean particle size.

5 New porous organic polymers of reduced particle size produced by the cutting process have also been discovered. In brief, the new products produced by the process have a non-spherical geometry, typically elongated and/or a length to diameter to width aspect ratio greater than one and a high surface area. The products find use, for example,
10 as additives in lead acid battery elements and in combination with functional agents such as additives for use in polymer coatings, films and composites and bioactive agents in slurry and fixed bed processes and environmental processes.

 A new battery element, which improves utilization
15 efficiency of the active material in a lead acid battery has been discovered. In brief, the battery elements include the addition of macroporous containing organic particle additives produced by the process of this invention to the active material in the positive or negative plates of a lead
20 acid battery to improve overall utilization efficiency and the utilization of sulfuric acid electrolyte during discharge of the battery.

Detailed Description of The Invention

 In one broad aspect, the present process reduces the
25 mean particle size of resilient porous organic polymer particles having open cell pores comprising the steps of forming an aqueous particle slurry comprising a major amount of water and a minor amount of said organic polymer particles wherein said water is present in a least a part of
30 the internal pores of the particles to provide a degree of resistance to particle compressibility and in addition, external to said particles to form a slurry. The slurry is

09753544-133700

subjected to a cutting action by contact with a plurality of cutting surfaces to reduce the mean particle size of the particles. The particles of reduced mean particle size are then recovered typically using conventional separation processes.

5 The porous organic polymer particles typically have open cell pores, i.e., pores that are interconnected and open to the outer surface, and are resilient, i.e., the particles can be compressed and resist permanent deformation under low or even moderate forces of compression. Typically, the porous organic particles have at least about 40%
10 porosity, more typically, at least about 60% porosity, i.e., the volume of the pores represent such percentage of the total volume of the particles typically from the standpoint of the average percent porosity of the particles. The average pore size distribution of the particles can
15 vary over a wide range, typically varying from about 0.02 microns to about 15 microns, more typically, from about 0.03 microns to about 12 microns and still more typically from about 0.75 microns to about 10 microns. The organic porous particles prior to size reduction typically have an average
20 particle-diameter of greater than about 2,000 microns, typically greater than about 1,000 microns, although, particles having an average diameter greater than 400 microns can be processed within the process of this invention. Particles produced by the process of this
25 invention have a reduced average particle size typically less than about 150 microns, more typically less than about 100 microns and still more typically less than about 75 microns or even less than about 50 microns.

30 The chemical composition of the porous organic polymers can vary widely and include polyolefins such as polypropylene and high and low-density polyethylene, nylons, ethylene vinyl acetate, polycarbonate, acrylonitrile

polymerized with styrene and/or butadiene and the like. One of the substantial advantages of the process of this invention is that porous organic polymers, which are hydrophobic, i.e., not significantly water wet, can be processed according to the process of this invention to reduce the average mean particle size of the porous particles.

In the process of this invention, the porous organic polymer particles are combined with a major amount of water to form an aqueous particle slurry. As set forth above, the porous organic polymers have open cell porosity, which allows water to be present in at least a part of the internal pores of said particles. It has been found that the presence of such water provides resistance to particle compressibility and enhances the effect of a cutting action to reduce the mean particle size of the porous particles. Typically, water will occupy at least about 10% more preferably at least about 50% of the pore volume of the particles or even greater than about 85% of the volume of the pores within said particles. It is preferred to have water present in the internal pores at a percent of the volume of the internal pores, which enhance the resistance to particle compressibility and in addition, which aids in the formation of an aqueous particle slurry, i.e., produces a higher density particle.

The aqueous particle slurry comprises a major amount of water said major amount of water being that water which is part of the internal pores of the particles and also that water which is external to said particles to form a slurry. Typically, the combined internal and external water represents at least about 80% of the total weight of the slurry, i.e., water and particles, i.e., the weight of particles on a dry basis, typically greater than about 85%

and more typically and preferred greater than about 90wt% basis the total weight of the slurry.

The aqueous particle slurry can be formed by combining porous organic polymers, typically in a dry form, with water under mixing conditions. Depending on the pore volume of the organic porous polymers, the density of the porous polymers can be significantly less than water such as less than 0.5gm per cc. In order to enhance the presence of water in the internal pores of the porous particles, a vacuum can be applied, with mixing, to aid in wetting out of the porous polymers. In addition and particularly when the organic polymers have hydrophobic character, a small amount of a surfactant, such as a non-ionic surfactant, can be added to the aqueous slurry to enhance wetting out of the internal surfaces of the pores of the particles and the presence of water within the internal pores. The use of surfactants such as hydrocarbon or fluorosurfactants and other chemical modifiers to assist in such change of polymer surface properties are well within the skill of the art.

Further, additional components that can modify the surface of the pores can also be added to the slurry, such as for binding or association of one or more functional release agents in the product. It has been found that one or more components can be distributed on the internal surfaces of the pores, thereby enhancing the properties of the functional agents. The aqueous particle slurry is subjected to a cutting action by contact with a plurality of cutting surfaces to reduce the mean particle size of the particles. As set forth above, the porous organic particles are resilient. The term resilient refers to particle compressibility when subjected to an external force or pressure at the process conditions of temperature and pressure

30 when the particles are subjected to the cutting action at the cutting surface. Thus, for example, the temperature of the particles may increase at the cutting surface as heat is generated during the cutting action. The term resilient refers to the condition of the particles under the conditions of temperature and pressure when the particles are in contact with the cutting surface. In one embodiment of the process of this invention the liquid particle slurry is fed to the center of a high speed rotating impeller.

5 Centrifugal forces then move the particles outward to cutting surfaces where the particles are in contact with the cutting edges of a stationary cutting head. The cutting action reduces the average mean particle size of the porous organic particles. It is preferred that the cutting
10 surfaces be stationary with the slurry being fed to a rotating non-cutting slurry distribution means, such as a rotating impeller. The term rotating cutting action includes those processes wherein the cutting surfaces are stationary.

15 One of the substantial advantages of the process of this invention is that difficult to process resilient porous organic polymers can be processed and achieve size reduction typically at relatively short residence times, i.e., a porous organic polymer particle is in contact with the cutting surfaces typically less than 15 seconds,
20 more typically, less than 5 seconds and even more typically less than 1 second. One of the further advantages of the process of this invention is the ability to produce non-spherical particles of reduced average mean particle size. As set forth above, many additive and functional agent type applications have a preference for a non-spherical geometry, i.e., one or more of the dimensions of

0075294-133700

25 length, width and thickness, i.e., height are different and
high surface area. The process of this invention can
produce non-spherical porous polymer particles of reduced
30 average mean size having varying length to width to height
ratios, i.e., the particles can be elongated and non-
spherical.

The porous organic polymer particles after size
reduction can be recovered by conventional processes.
Typical examples of such recovery processes are filtration,
such as rotary and vacuum filters, screens such as vibrating
screens and centrifuges. The choice of the recovery process
can be varied depending on the end use application of the
5 recovered particles. For example, a typical additive for
use in lead acid batteries may have an acceptable moisture
content of from about 30 to 40 wt%. In other end use
applications substantial or complete dewatering of the
internal pores may be required. The above recovery
10 processes typically remove about 90%, typically greater than
95% of the external water that forms the aqueous particle
slurry and can produce a dry free flowing powder. The
percentage of the internal water removed will vary according
to the end use application. It is contemplated within the
15 scope of this invention that there can be substantial
dewatering of the internal pores including dewatering of
from about 85 to about 100%, more typically from about 90 to
100% of the internal water, i.e., less than about 10wt%
moisture. As set forth above, the degree of the dewatering
20 of the internal pores relates to the final end use
application of the particle products.

As is recognized by those of skill in the art, a number
of the above recovery processes have the capability to
recover particles of different size classifications. Thus
25 for example, the product might be recovered at a certain top
size, for example less than about 150 microns or less than

As set forth above, the porous polymers can be reloaded with a functional agent such as additives including meltable solids and dispersions by mixing the organic porous polymers of reduced particle size with the agent. The porous structure typically acts like tiny sponges with the ability to absorb such liquids typically up to several times their own weight. It is believed that the pores of the porous polymers are filled by capillary absorption. After the agent is added to the porous polymer, the system generally remains dry and free-flowing. In order to maximize the adsorption of the liquid additive, it is preferred that the internal water be substantially removed from the porous polymer prior to addition of the liquid additive. The loaded porous polymers can then be used in many applications and combined with other polymers to provide an additive concentrate as a free-flowing powder. Typical low melting additives, which can be incorporated into the porous polymers are anti-static agents, slip and anti-block agents, mold release agents, permanent lubricants, anti-fog agents, antioxidants, light stabilizers, nucleating agents, peroxides, biocides, fragrances, insecticides, pharmaceuticals, agricultural agents, pheromones and the like. As is known by those of skill in the art, the agents themselves may be liquid or if solid, can be added to a liquid carrier such as an organic or water based carrier in

which the additive is dissolved, emulsified and/or dispersed in order for the agent and carrier to be absorbed in the pores of the polymer. The pore diameter of the polymer is generally selected in order to achieve a rapid uptake of the liquid additive material and which also produces, in general, a dry and free-flowing powder. Typically, loading capacities greater than 50% or even up to 70% or more can be loaded with the liquid additive. Further, additional slow release agents, such as gels, can be added, for example, to the above agents.

The external and internal surfaces can also be modified during manufacture to produce a hydrophilic character and/or a combination of hydrophilic and hydrophobic character and surface properties providing for complex functionality.

The porous polymers can also be used for loading with agents for use in a variety of end-use applications. For example the porous polymers can be reloaded with one or more bioactive species for use in environmental and/or chemical processing type applications, including bioremediation, bioaugmentation, waste water treatment and other chemical processes. The porous polymers have the unique property of having surface modification as required for a given application and for ease separation from polymer powder aqueous slurries in, for example, slurry processing.

Porous polymers can be added to enhance bioremediation systems or bioprocesses. Depending on the application, the porous polymers may or may not be preloaded with bacteria for specific biological activities. Potential biological processes and/or bioremediation systems for the use of porous polymers are set forth below. Porous polymers can be particularly effective in the creation of what is known as in situ reactive barriers. Reactive barriers are engineered systems emplaced in the direct flow of groundwater to degrade or chemically transform contaminants. These barriers

are typically permeable so that the groundwater can continue on its natural path after the contaminants have been removed. The inherently small size of the porous polymer particles is a significant advantage for in situ applications since the barriers are often emplaced as a slurry wall either through excavation and backfilling or through direct injections of material into the aquifer itself. A porous polymer slurry can be placed in the aquifer through wells, a significant advantage for deeper contaminated sites. In addition a surfactant with the porous polymer slurry can be pumped as an aqueous slurry. Typical contaminants are hydrocarbons, chlorinated organics and heavy metals. Each type of contaminant has unique needs that can be effectively addressed by the use of a porous polymer barrier. The porous polymers can be used as is or could be pre-loaded with bacteria of known contaminant transforming capability to seed the aquifer, resulting in a locally high concentration of bacteria with the proper metabolic capabilities.

Further, the porous polymers can be used as hydrocarbon barriers. Many hydrocarbons are known to be very biodegradable in the presence of oxygen (e.g. BTEX compounds -benzene, toluene, ethylbenzenes, and xylene) i.e. natural biodegradation of these compounds in aquifers. There is another compound that can lend itself to reactive barriers. This compound is methyl tertiary butyl ether (MTBE -a relatively recent gasoline additive). MTBE is a highly mobile organic contaminant that is very resistant to biodegradation. A few organisms have been isolated that have degrading capability. Pre-loading the porous polymers with an MTBE degrading organism and employing it as a barrier for MTBE in the groundwater can be a viable treatment technology.

Chlorinated solvents (e.g. perchloroethylene and trichloroethylene) are recalcitrant compounds that can be biodegraded in the subsurface. These compounds are typically degraded in the absence of oxygen by natural bacteria through the addition of a carbon source such as lactate. The bacteria generate reducing power from organic substrates such as lactate.

For chlorinated solvent treatment, the use of porous polymers can enhance the remediation process in a number of ways. First, the porous polymers can be used as a carrier for bacteria that have been adapted for high activity against chlorinated solvents. Second, the chlorinated solvents like hydrocarbons are somewhat hydrophobic and can preferentially partition onto the porous polymers so that the biological removal processes would also be enhanced by the abiotic sorption of chlorinated solvents to the polymer. Finally, as set forth above, chlorinated solvent biodegradation typically requires the use of an organic substrate for reducing power. These organic substrates (typically an organic acid such as lactate) can be added to the porous polymers to yield a time-release effect. The substrate can be slowly released in very close proximity to the chlorinated solvents concentrated at the porous polymer surface.

It is well known that the mobility of a variety of heavy metals can be significantly reduced through biological activities. These activities fall into two categories that include direct metal reduction and metal sulfide precipitation. With direct microbial reduction, heavy metals including chromium, the bacteria in the presence of an organic substrate can reduce uranium, technetium, and cobalt. When reduced, these metals form insoluble precipitates that can remain trapped within the porous polymer barrier. Metal sulfide precipitation relies on the

use of sulfate reducing bacteria to produce hydrogen sulfide. The sulfide ion reacts with many heavy metals (including lead, mercury, copper, cadmium, zinc, and iron) to form insoluble precipitates. The heavy metal barrier can have many of the same characteristics of the chlorinated solvent barriers. Bacteria (sulfate or metal reducing) can be added to the porous polymer matrix to increase rates of metal transformation. In addition, organic substrates are typically necessary and can be added to the porous polymers for a slow release process.

Animal waste lagoons are difficult to control regarding emissions of odorous gasses that result from anaerobic microbial activity in the waste lagoon. These odorous gasses can typically be degraded by bacteria under aerobic conditions. Currently, attempts have been made to cover the lagoons, collect the noxious gasses and treat them in a biofilter containing aerobic bacteria. Covering the lagoons with a gas impermeable barrier is costly and operating a biofilter can be difficult. A significant advance is the use of floating porous polymer products of this invention to increase the surface area of the interface between the water of the lagoon and the atmosphere. The porous polymers can provide a high surface area interface between the anaerobic lagoon and the atmosphere. The porous polymers can be pre-loaded with bacteria or can be colonized by naturally occurring bacteria from the lagoon itself. The porous polymers can form a moist floating cover for the lagoon and this cover has a high surface area available for biological activity. In addition the porous polymers cover can be open to the atmosphere to provide oxygen exchange rates necessary to consume the odorous gases.

Certain industrial wastewater treatment facilities can use powdered activated carbon (PAC) as a process-enhancing additive to activated sludge treatment systems. The PAC is

added to the system for two primary reasons: 1) the solid support provides a surface for attachment of bacteria thus promoting improved biomass retention and 2) the PAC provides an adsorption mechanism for the removal of hazardous compounds. However the PAC sinks, is collected and makeup PAC added. The porous polymers can act in much the same manner as the PAC. However, the density of the porous polymers even above 1.0 and its dispersal properties can be varied and its ability to be easily recovered such as by aeration/flotation, screens and hydroclones provides substantial advantages to waste water treatment processes. The porous polymers can be loaded with bacterial cultures acclimated to particular hazardous compounds to facilitate a high activity against specific hazardous compounds.

Bioactive species such as bacteria and other microorganisms associated with the porous particles, i.e., bioparticles can be used in a variety of applications. These include the biotreatment of aqueous waste streams, the biofiltration of gases, biosynthesis of fine and commodity chemicals, and other uses for which supported bacteria are suitable. The bioparticles have a catalytically efficient amount of microorganism associated with the particles.

In the fields of biotechnology and bioremediation, for example, bioactive species are often associated with a support to more effectively utilize the bioactive species. As used herein, the term "associated with" refers to adsorption, such as, physadsorption or chemadsorption, ligand/receptor interaction, covalent bonding, hydrogen bonding, or ionic bonding of bioactive species to the porous particles. Bioactive species include enzymes, organic catalysts, ribozymes, organometallics, proteins, glycoproteins, peptides, polyamino acids, antibodies, nucleic acids, steroidal molecules, antibiotics,

antimycotics, cytokines, carbohydrates, oleophobic and lipids, microorganisms having cells, such as, reptilian cells, amphibian cells, avian cells, insect cells, planktonic cells, cells from non-mammalian marine
30 vertebrates and invertebrates, plant cells, microbial cells, protests, genetically engineered cells, and organelles, such as mitochondria.

Other examples of a suitable microorganism include bacteria from the following genera: Pseudomonas, Acinetobacter, Mycobacterium, Corynebacterium, Arthrobacterium, Bacillus, Flavobacterium, Nocardia, Achromobacterium, Alcaligenes, Vibrio, Azotobacter,
5 Beijerinckia, Xanthomonas, Nitrosomonas, Nitrobacter, Methylosinus, Methylococcus, actinomycetes and Methylobacter. Additional microorganisms include members of the fungi, yeast, algae and protozoans.

The bioparticles can be used in the biotreatment of an
10 aqueous waste stream or contaminated vapor as packing materials for bioreactors. Microorganisms with specialized metabolic capabilities can be used to colonize or adhere to the porous particles and thus serve as biocatalyst for the decontamination of waste streams. The porous bioparticles
15 in a bioreactor increases the total surface area for high microbiological cell densities which result in chemical degradation rates much higher than those of conventional waste treatment systems. The bioparticles can provide a means of controlling conditions, which favor microbial
20 degradation of target compounds in for example a bioreactor. For example, parameters such as pH, oxygenation, nutrient concentrations, temperature, salinity, electron donors and co-metabolic substrates can be controlled. A bioreactor can be run under anaerobic and aerobic conditions. The waste
25 stream can enter the base of the reactor such that the flow is upward or it can enter the top of the bioreactor and the

00222146825260

5

10

15

20

Microorganisms, used in the practice of this invention, can be anaerobic and aerobic microorganisms selected to degrade target pollutants in ways well known in the art. The microorganisms can be employed as a pure strain or as a consortium of microorganisms. In preferred embodiments of the invention, aerobic microorganisms are employed. Although anaerobic microorganisms often degrade pollutant materials at a slower rate than aerobic microorganisms, an anaerobic process may be required to degrade a pollutant or an intermediate product to a material, which is susceptible to aerobic degradation to a non-toxic level or to a

25 non-pollutant material. For example, ammonia can be
remediated anaerobically first and then aerobically to the
final products. Useful microorganisms may vary widely and
may be naturally occurring microorganisms or may be
genetically engineered microorganisms. The only requirement
30 is that microorganisms are capable of metabolizing the
target pollutant(s) to the required effluent levels over the
required period of time. In the preferred embodiments of
the invention, microorganisms are obtained from the
pollutant-containing waste stream or from soil, which has
been in contact with the waste stream.

In the operation of the process, the cell content of
microorganisms (including extracellular proteins produced by
5 microorganisms) is an amount, which is sufficient to reduce
the pollutant content to the desired concentration level
within the desired retention time. In the preferred
embodiments of the invention, cell content of microorganisms
is at least about 0.5% by weight based on the total weight
10 as bioparticle and in the most preferred embodiments of the
invention is from about 0.5% by weight to about 15% by
weight based on the aforementioned basis. Among these
particularly preferred embodiments most preferred are those
embodiments in which the cell content of microorganisms is
15 from about 0.5 to about 10% by weight based on the total
weight bioproducts.

As set forth above, the term "bioactive species" is
used broadly, to include for example bacteria, fungi, spores
derived therefrom and cells derived from multicellular
20 organisms.

The bioactive species can be retained on the porous
particle by a variety of physical and/or chemical means e.g.
adsorption, entrapment, ionic linking, chemical bonding.
The cells are in practice found to be associated at least
25 within the pores of the porous polymer.

Since there are essentially no closed pores in the particle and since the pores are generally fully interconnected by channels the biological cells are able to enter pores easily, so that a high loading of the particles can be achieved and entry of the species into the particles is easily achieved. Indeed, it is possible to introduce the species into the particles passively, e.g. by merely shaking the particles in a suspension of species cells.

Instead of passive introduction of cells, the cells may be introduced into the porous particles by passing a cell suspension through a packed or expanded bed constituted by the porous particles.

As set forth above, the bioactive agents used in the present invention can be selected from the group comprising microbes, yeast cells, fungi, animal cells, plant cells, and mixtures thereof. In some instances the cells have been found to adsorb directly onto the surface of the porous particles, but in other cases it may be necessary to provide a chemical linkage to bind the cells. Such modification can be done during the reduction of the size of the porous particles or at a later stage. In such cases porous particles whose surfaces have been chemically modified have been found appropriate to provide chemical binding sites for the cells. Whatever method of attachment of the cells is employed, the use of the present porous particles have been found particularly appropriate as the cells can be associated within the interconnecting pores providing some or all of the advantages mentioned above.

A particular advantage found is that cells can adapt their morphology to create strong bonds to the polymeric particle. Thus there may be initially only a loose interaction with the particle. This initial interaction may be a process of physical adsorption at the polymer surface,

25 i.e. without covalent bonding and without ionic bonding.
Subsequently the cells may become chemically attached by
adaption of the cells themselves.

Large pores in the porous particles will allow large catalytic species to be supported within these pores. Of particular interest is the use of living cells, e.g. bacteria, as catalysts: bacteria are large, with typical dimensions on the order of 1 micron or greater, and thus will not fit in smaller pores. While bacteria will form colonies on non-porous materials, the additional surface area, which is available within the pores foster larger bacterial populations. Further, bacteria in pores can be protected from transient upsets in the external medium because diffusion into the pores can be moderated. This is particularly true of upsets characterized by a sudden high concentration of some compound which may be toxic to the bacteria or by sudden changes in pH, ionic strength or toxic concentration of an organic or inorganic component of a waste stream. Bacteria supported on porous particles may also be resistant to longer-term upsets, such as temporary oxygen or nutrient starvation caused, for example, by equipment failures.

A further preferred embodiment is the use of resilient porous organic polymers produced by the process of this invention as additives in battery plates.

As set forth above, it is preferred that the porous substrate particles have sufficient macroporosity and percent apparent porosity for the utilization of the electrolyte sulfuric acid contained in the pores during discharge of the active material. Further, as set forth above, the preferred mean macropore diameter is from about 0.075 microns to about 10 microns and still more preferably from about 0.1 to about 5 microns. Particularly preferred porous particles that exhibit sufficient macroporosity are

30

25 cutting surfaces arranged in a circular retaining device.
It was estimated that for the 400-micron powder, the total
solution, including both internal and external water was 95%
with the remainder being 5% as dry powder. For the 1500-
micron and 200-1000 microns powders, the total solution of
30 the internal and external water was estimated to be 96% with
the balance being 4% as dry powder.

EXAMPLE 1

The 400-micron powder slurry was fed into a Comitrol
processor model 1700 with an impeller speed of 11,925 RPM.
The cutting head was identified as 212084-1⁰. 1 1/2 lbs. of
dry material in slurry form was fed into the rotating
5 impeller at a time of approximately 5-10 seconds. The
temperature in was 70°F and out was 75°F. A product was
recovered in which 64% of the product passed through
120-mesh sieve. The recovered material was recycled through
10 the model 1700 but with a cutting head identified as
216084-1⁰. 90% of the recovered product passed through
120-mesh. The temperature increased from 75°F in to 80°F
out.

EXAMPLE 2

15 Example 1 was repeated except that the powder was 200-
1000 microns and the cutting head was 190804-2⁰. The
recovered product passed 100% through a 45-mesh sieve. The
product was then processed through the same Comitrol model
1700 but with a cutting head identified as 212084-1⁰. 54%
20 of the product passed through a 120-mesh sieve. This
recovered product was again passed through the model 1700
using a cutting head identified as 216084-1⁰. 86% of the
product passed through a 120-mesh sieve. The temperature
from the initial pass to the final pass went from 70°F to

25 79°F. The total single particle contact cutting time for
the three passes was less than 30 seconds.

EXAMPLE 3

Example 2 was repeated except the polypropylene powder
was less than 1500 microns. After three passes using the
30 same sequence of cutting head as in Example 3, 89% of the
product passed through a 120-mesh sieve.

EXAMPLE 4

The product of Example 3 was dried in a ribbon drier at
a temperature of from 300 to 325°F for a time of from two
and one-half to three hours. The moisture content of the
5 final product was approximately 10wt%. The product was
divided into two portions. One of which was contacted with
a UV stabilizer used in polycarbonate polymers. The
stabilizer filled the pores to approximately 90% of the
available pore volume. The product is useful for
10 compounding with polymer products to distribute the UV
stabilizer in the product.

EXAMPLE 5

The second product of Example 4 dried to 10wt% was
contacted with a culture of Pseudomonas, which was
15 continuously passed through the porous product until
bioactive bacteria growth was evident on the porous
particles. The porous particles can be used for the
degradation of aromatic compounds such as phenol.

While this invention has been described with respect to
20 various specific examples and embodiments, it is to be
understood that the invention is not limited thereto and
that it can be variously practiced within the scope of the
following claims.
